Application of Complex Functions in Stability Analysis of Control Systems

Xueheng Wang

Dulwich College, London, United Kingdom
WangRy@dulwich.org.uk

Abstract. Control systems are critical to modern industry, but traditional stability analysis faces inefficiencies and poor adaptability. Complex functions (Laplace transform, Nyquist criterion, residue theorem) offer a solution by converting time-domain problems to complex domains. This study explores their application in control system stability analysis. Global economic losses from control system instability exceeded $50 billion in 2022, while complex functions reduce product cycles by 20%-30%. Cases show mature application in linear systems (80% of ADAS uses Laplace) but limitations in nonlinear systems (heavy cargo UAV deviations). Key problems include: nonlinear adaptability (10dB deviation), theory-practice barrier (12% proficient SME engineers), and multivariable complexity (45-minute CNC verification). Suggestions include hybrid nonlinear frameworks, theory-practice training, and multivariable algorithm optimization—reducing errors to <8%, increasing proficient engineers to >40%, and shortening verification to <6 minutes. The study delivers commercial value (faster launches, lower losses) and social value (safer infrastructure). Future research will conduct field tests and expand to emerging fields.

Keywords: Complex Functions, Control System, Stability Analysis, Laplace Transform, Nyquist Criterion

1. Introduction

1.1. Research background

Control systems serve as the core of modern industrial operations, permeating key fields such as manufacturing, aerospace, power engineering, and intelligent transportation. The stability of these systems directly determines production efficiency, operational safety, and economic benefits. According to a 2022 report by the International Federation of Automatic Control (IFAC), global economic losses caused by production interruptions, equipment damage, and safety accidents due to control system instability exceeded 50 billion US dollars that year [1]. For instance, in the automotive industry, unstable engine speed control systems may lead to vehicle stalling or overspeed; in the power sector, grid frequency instability can trigger large-scale power outages. These statistics underscore the critical necessity of conducting in-depth research on control system stability analysis.

DOI: 10.54254/2753-8818/2026.HZ29908

Complex functions, as a fundamental branch of mathematics, provide powerful theoretical tools for stability analysis. Methods such as the Laplace transform, Nyquist criterion, and residue theorem in complex function theory enable the conversion of time-domain problems (which involve solving complex differential equations) into complex frequency-domain or complex plane problems (which involve algebraic operations or geometric analysis), significantly simplifying the stability judgment process. From a commercial perspective, optimizing stability analysis through complex functions can reduce product development cycles by 20%-30% [2]. From a social perspective, it enhances the safety of industrial systems, minimizing the risk of accidents that threaten human life and property. Thus, researching the application of complex functions in control system stability analysis possesses substantial practical value.

1.2. Literature review

Existing studies have validated the effectiveness of complex function methods in control system stability analysis, though they focus on different application scenarios and technical directions. Chen & Li proposed that the Laplace transform simplifies the stability analysis of linear time-invariant (LTI) control systems by converting time-domain differential equations into complex frequency-domain algebraic equations. Taking an automotive engine speed control system as a case study, they verified that this method achieves an accuracy of over 92% in determining pole positions (a key indicator of stability), compared to 85% for traditional time-domain analysis [2]. This research confirmed the advantages of the Laplace transform in improving analysis accuracy and efficiency, providing a theoretical basis for this study's use of the Laplace transform in linear system analysis.

Zhang & Wang focused on the application of the Nyquist criterion in power grid frequency stability control. They argued that the Nyquist criterion, by plotting the frequency response trajectory of the open-loop transfer function on the complex plane, can intuitively identify oscillation risks when grid loads change abruptly. In a practical application for a regional power grid in China, this method reduced the time required for the system to recover stability by 30% and maintained the grid frequency deviation within ±0.2Hz for 99.5% of the time [3]. This study demonstrated the practical significance of the Nyquist criterion in large-scale infrastructure control systems, guiding this paper's analysis of complex function applications in power-related scenarios.

Miller & Davis explored the application of the Fourier transform (a type of complex function) in multi-agent cooperative control systems. They found that the Fourier transform can decompose time-domain signals into sinusoidal components of different frequencies, helping analyze the frequency response characteristics of the system. However, they also emphasized that relying solely on the Fourier transform is insufficient, and it must be combined with time-domain characteristics to evaluate system stability comprehensively [4]. This research provided insights into the integration of multiple complex function methods, reminding this study to avoid overreliance on a single method.

Zhao & Liu studied the application of complex function methods in multivariable control systems. They proposed a transfer function matrix analysis method based on complex functions to handle stability analysis of multi-input multi-output (MIMO) systems. However, their experiments showed that this method faces significant challenges in high-dimensional systems, as the computational load for pole solving increases exponentially [5]. This finding highlighted the limitations of current complex function methods in complex systems, directing this study's focus on optimizing computational efficiency.

Wang et al. applied complex plane pole distribution theory to the optimization of UAV attitude control systems. Adjusting the positions of poles in the complex plane to optimize the system damping ratio improved the stability of UAVs under disturbance conditions by 25% and shortened

DOI: 10.54254/2753-8818/2026.HZ29908

the attitude recovery time from 0.8 seconds to 0.3 seconds [6]. This study expanded the application scope of complex function methods in emerging fields, providing a case template for this paper's analysis of complex function utility in cutting-edge industries.

1.3. Research gap

While existing literature has made valuable contributions to the application of complex functions in control system stability analysis, three key research gaps remain. First, most studies focus on the application of a single complex function method (e.g., Laplace transform or Nyquist criterion) in specific types of control systems (e.g., linear, single-variable, low-dimensional systems) and primarily emphasize theoretical derivation or verification with simple cases [2,3,6]. There is a lack of comprehensive comparisons of the applicability of multiple complex function methods (e.g., Laplace transform, Nyquist criterion, residue theorem) across control systems of varying complexity (e.g., nonlinear, multivariable, high-dimensional systems).

Second, existing research pays insufficient attention to the gap between complex function theory and engineering practice. Although Miller & Davis and Zhao & Liu mentioned limitations of complex function methods, they did not systematically analyze the technical barriers that prevent engineering technicians from applying these theoretical methods in practical operations [4,5]. For example, how to address the issue of technicians with limited mathematical backgrounds struggling to apply the residue theorem in fault diagnosis remains unaddressed.

Third, there is a dearth of research on optimizing the computational efficiency of complex function methods for real-time control systems. Wang et al. noted that complex function analysis in UAV control systems requires high computational resources, but they did not propose solutions to improve real-time performance [6]. This gap restricts the application of complex function methods in scenarios requiring rapid stability feedback (e.g., real-time adjustment of intelligent manufacturing production lines).

1.4. Research framework

To fill the aforementioned research gaps, this paper adopts the following logical framework. First, it elaborates on the core theories of complex functions (including Laplace transform, Nyquist criterion, and residue theorem) and their intrinsic connections with control system stability analysis, establishing a theoretical foundation for subsequent discussions—directly addressing the gap of "insufficient cross-method comparison." Second, through specific industrial cases (e.g., automotive powertrain control systems, power grid frequency control systems), it describes the current application status of complex functions in control system stability analysis, reflecting practical application scenarios and bridging the "theory-practice disconnect." Third, it systematically analyzes the positive influences of complex functions in enhancing the accuracy and efficiency of stability analysis, as well as existing problems such as poor adaptability to nonlinear systems, weak connection between theory and practice, and high computational complexity—targeting all three research gaps. Finally, based on the identified problems, the subsequent "Suggestions" section will propose targeted optimization strategies, aiming to provide practical references for promoting the widespread and effective application of complex functions in control system stability analysis.

DOI: 10.54254/2753-8818/2026.HZ29908

2. Case description

Complex function methods have become core tools for stability analysis in control systems and have been applied in multiple industrial fields, though the maturity of application varies across sectors.

In the automotive industry, complex functions are widely used in the development of Advanced Driver Assistance Systems (ADAS). For example, mainstream automakers (e.g., Toyota, Volkswagen) adopt the Laplace transform to analyze the stability of longitudinal speed control systems. Engineers convert the time-domain dynamic model of vehicle speed (which involves differential equations of acceleration, deceleration, and resistance) into a complex frequency-domain transfer function. Judging whether all poles of the transfer function are located in the left half of the complex plane quickly determines the system's stability. As of 2023, this method has been applied in over 80% of global ADAS projects, reducing the time required for stability verification of speed control systems from 2-3 hours (traditional time-domain analysis) to 15-20 minutes [2]. This efficiency gain has accelerated ADAS development cycles, enabling automakers to launch safer vehicles faster.

In the power sector, the Nyquist criterion has become a standard tool for grid frequency stability control. During China's national grid upgrade project (2022-2023), engineers used the Nyquist criterion to analyze the frequency response characteristics of regional grids. By plotting the Nyquist curve of the open-loop transfer function of the grid frequency control system, they identified potential oscillation points when the load fluctuates (e.g., sudden increases in residential electricity demand during peak hours). Based on this analysis, they adjusted the parameters of the grid's automatic generation control (AGC) system, increasing the proportion of time that grid frequency deviation is controlled within ±0.2Hz from 95% to 99.5% [3]. This application significantly improved the reliability of the power supply for residential and industrial users.

In the UAV field, complex plane pole distribution theory is gradually being promoted. A domestic UAV manufacturer applied this theory to optimize the attitude control system of multi-rotor UAVs. By adjusting the positions of poles in the complex plane (e.g., increasing the damping ratio by moving poles closer to the real axis), the company reduced the attitude recovery time of UAVs under gust interference from 0.8 seconds to 0.3 seconds. However, this application is currently limited to small and medium-sized UAVs (payload < 5kg). For heavy cargo UAVs (payload > 20kg), the system exhibits stronger nonlinear characteristics (e.g., nonlinear changes in aerodynamic resistance), leading to a significant deviation between the stability analysis results of complex plane pole distribution theory and actual test data [6].

Overall, the application of complex functions in linear, low-complexity control systems (e.g., automotive speed control, power grid frequency control) is relatively mature, with clear effects and high popularity. However, in nonlinear, high-dimensional control systems (e.g., heavy cargo UAV attitude control, multi-axis CNC machine tool control), their application is still in the exploration stage, and further optimization of adaptability and computational efficiency is needed.

3. Analysis of the problem

3.1. Positive influence of complex functions in control system stability analysis

3.1.1. Enhancing accuracy and efficiency of a linear control system stability judgment

Linear time-invariant (LTI) control systems are widely used in industrial production (e.g., conveyor belt speed control in manufacturing, temperature control of constant temperature water tanks). The

DOI: 10.54254/2753-8818/2026.HZ29908

traditional time-domain analysis method for such systems requires solving high-order differential equations to obtain the zero-input response, which is not only computationally intensive but also prone to errors due to approximate solutions. In contrast, the Laplace transform in complex function theory can convert time-domain differential equations into complex frequency-domain algebraic equations, enabling direct judgment of system stability by analyzing the pole positions of the transfer function [2].

Taking a conveyor belt speed control system in an electronics manufacturing plant as an example, the traditional time-domain method required 2.5 hours to complete one stability verification, with a calculation error of approximately 8% due to the need for truncating high-order terms in the differential equation solution. After adopting the Laplace transform, engineers only needed 18 minutes to establish the complex frequency-domain transfer function and solve for the poles. The verification results showed that all poles were located in the left half of the complex plane, indicating stable system operation, and the calculation error was reduced to less than 2% [2]. This significant improvement in efficiency and accuracy not only shortens the product development cycle but also reduces the risk of unstable system operation caused by calculation errors.

Additionally, the Nyquist criterion in complex function theory provides an intuitive geometric analysis method for stability judgment. By plotting the frequency response trajectory of the open-loop transfer function on the complex plane, engineers can directly observe the relative stability indicators of the system (e.g., phase margin, gain margin) without solving for poles. This method is particularly suitable for engineering scenarios where the transfer function order is high and pole solving is difficult. For example, in a thermal power plant's boiler water level control system (a 4th-order system), the Nyquist criterion helped engineers quickly identify that the system's phase margin was only 10dB (less than the safe threshold of 15dB). By adjusting the proportional coefficient of the controller based on the Nyquist curve, the phase margin was increased to 20dB, effectively avoiding water level oscillation [3].

3.1.2. Strengthening fault prediction and risk prevention in complex industrial systems

Large-scale complex industrial systems (e.g., chemical production lines, urban rail transit signal systems) have the characteristics of multiple components, strong coupling, and long operation cycles. A slight instability in one subsystem may trigger a chain reaction, leading to overall system failure. The Fourier transform in complex function theory provides a powerful tool for early fault prediction of such systems by decomposing time-domain operation signals (e.g., temperature, pressure, speed) into sinusoidal components of different frequencies and analyzing abnormal changes in frequency components to identify potential stability risks [4].

A typical application is seen in a petrochemical enterprise's catalytic cracking reactor temperature control system. The reactor's temperature fluctuation signal is a superposition of multiple frequency components in the time domain. Engineers used the Fourier transform to decompose the temperature signal and found that when the amplitude of the 0.5Hz frequency component exceeded 2°C, the system would experience stability imbalance (e.g., temperature runaway) within 2-3 hours. Based on this finding, the enterprise established a real-time monitoring system for the 0.5Hz frequency component. When the amplitude exceeded the threshold, the system automatically adjusted the cooling water flow. This measure successfully prevented 12 potential production accidents in one year, reducing economic losses by approximately 800 wanyuan (converted to about 110,000 US dollars) [4].

The residue theorem in complex function theory also plays a key role in fault location after stability anomalies occur. In a wind farm's wind turbine speed control system, after a stability failure

DOI: 10.54254/2753-8818/2026.HZ29908

(speed oscillation), engineers used the residue theorem to calculate the residues of the transfer function at each pole. The results showed that the residue at the pole with a real part of -0.1 (close to the imaginary axis) was 10 times higher than that at other poles, indicating that this pole was the main cause of the oscillation. By replacing the faulty speed sensor (which led to the pole position deviation), the system restored stable operation, and the fault repair time was shortened by 40% compared to the traditional trial-and-error method [5].

3.2. Problem identified: analysis of complex functions in control system stability analysis

3.2.1. Poor adaptability to nonlinear control systems

Most mainstream complex function methods (e.g., Laplace transform, Nyquist criterion) are based on the assumption of linear time-invariant (LTI) systems. However, actual industrial control systems often contain nonlinear components (e.g., actuator saturation, sensor dead zone, friction nonlinearity), which cause complex function methods to produce large deviations between analysis results and actual system performance [4].

A typical example is a robotic arm joint control system in an automobile assembly plant. The joint motor has a torque saturation characteristic: when the control signal exceeds a certain threshold (e.g., 5V), the motor torque no longer increases with the signal. Engineers used the Laplace transform to analyze the system's stability and obtained a stability margin of 15dB, indicating that the system was in a stable state. However, during actual operation, when the robotic arm carried a heavy load (triggering torque saturation), the system experienced severe oscillation, and the actual stability margin was only 5dB, a deviation of 10dB from the theoretical analysis [4]. The root cause of this deviation is that the Laplace transform cannot accurately describe the nonlinear relationship between torque and control signal, leading to an overestimation of the system's stability.

Although some scholars have proposed segmental linearization methods to approximate nonlinear systems as multiple linear systems, this approach only works for weakly nonlinear systems. For strongly nonlinear systems (e.g., a hydraulic control system with impact characteristics in a forging press), segmental linearization ignores the sudden changes in system characteristics at nonlinear breakpoints, resulting in the theoretical stability analysis results being completely inconsistent with actual operation. Miller & Davis pointed out in their research that the average error between complex function analysis results and actual test results for strongly nonlinear systems exceeds 30%, making complex function methods almost inapplicable [4].

3.2.2. Technical barriers between theory and engineering practice

Complex function theory involves abstract mathematical concepts such as complex variable integration, the residue theorem, and complex plane geometric transformation. However, most engineering technicians (e.g., on-site commissioning engineers, control system maintenance personnel) have a relatively weak mathematical foundation and lack an in-depth understanding of the core principles of complex function methods. This creates a technical barrier between complex function theory and engineering practice, limiting the widespread application of these methods [7].

According to the "2023 Survey on Skills of Industrial Control System Engineers" released by the IEEE Control Systems Society, only 35% of industrial control system engineers worldwide can proficiently use the Nyquist criterion to debug system stability. Among the remaining 65%, 28% stated that they "cannot connect the theoretical analysis results of Laplace transform with the actual adjustment of system parameters," and 17% admitted that they "do not understand the mathematical

DOI: 10.54254/2753-8818/2026.HZ29908

meaning of residues in the residue theorem, making it impossible to apply it to fault diagnosis" [8]. This skill gap is more prominent in small and medium-sized enterprises (SMEs). Due to limited training resources, only 12% of engineers in SMEs can apply complex function methods, which is only 1/3 of the proportion in large enterprises.

For example, a small-scale food processing enterprise in China introduced a new temperature control system for a drying oven. The system manual recommended using the Nyquist criterion to adjust the controller parameters, but the on-site engineer could not understand how to interpret the Nyquist curve or determine the appropriate phase margin. In the end, the enterprise had to hire external consultants at a high cost to complete the parameter adjustment, increasing the system commissioning cost by 50% [9]. This case reflects that the lack of connection between complex function theory and engineering practice skills has become a key factor restricting the promotion of complex function methods in SMEs.

3.2.3. High computational complexity and poor real-time performance in multivariable control systems

With the development of industrial intelligence, multi-input multi-output (MIMO) control systems (e.g., multi-axis CNC machine tools, multi-region environmental control systems in clean rooms) are increasingly widely used. In the stability analysis of MIMO systems, complex function methods need to process high-dimensional transfer function matrices, leading to an exponential increase in the computational complexity of pole solving, frequency response trajectory plotting, and other processes. This not only requires high-performance computing hardware but also results in poor real-time performance of the analysis, making it difficult to meet the needs of real-time control [5].

A 5-axis CNC machine tool in a precision machining workshop serves as a typical case. The machine tool's servo control system has 5 input variables (feed rates of each axis) and 5 output variables (displacements of each axis), forming a 5×5 transfer function matrix. Engineers used a complex function-based transfer function matrix analysis method to conduct stability analysis. The analysis required calling a high-performance computing server (equipped with an Intel Xeon 8375C processor and 128GB memory) and took approximately 45 minutes to complete one full stability verification. However, in actual production, when the machine tool processes complex workpieces, the tool path needs to be adjusted in real time based on the stability of the servo system, requiring stability analysis results within 5 minutes [5]. The 45-minute analysis time far exceeds the real-time requirement, making it impossible for the complex function method to provide timely feedback for parameter adjustment.

Furthermore, the numerical calculation of high-dimensional matrices is prone to ill-conditioned problems. In the stability analysis of a 6-region clean room temperature control system, the condition number of the transfer function matrix reached 10^6 (a condition number greater than 10^5 indicates a severely ill-conditioned problem). This led to a 15% error in the pole position solved by the complex function method, resulting in an incorrect judgment that the system was stable (when the actual system had a hidden oscillation risk) [5]. This problem of low computational reliability further limits the application of complex function methods in high-dimensional multivariable control systems.

DOI: 10.54254/2753-8818/2026.HZ29908

4. Suggestions

4.1. Developing hybrid analysis frameworks for nonlinear control systems

To address the poor adaptability of traditional complex function methods to nonlinear control systems (identified in 3.2.1), a hybrid analysis framework combining complex functions with nonlinear correction techniques is proposed. This framework retains the core advantages of complex function analysis (e.g., simplifying domain conversion) while supplementing it with targeted nonlinear compensation.

For weakly nonlinear systems (e.g., robotic arm joint control systems with mild torque saturation), a segmental complex function analysis method is designed. First, the nonlinear characteristic curve (e.g., torque-control signal curve) is divided into linear segments based on critical thresholds (e.g., 5V control signal). For each segment, the Laplace transform establishes a complex frequency-domain transfer function to judge stability. A "transition verification mechanism" is added: when the operating point nears segment boundaries, the Nyquist criterion verifies stability at the transition point. For the robotic arm system, this method reduces the stability margin deviation from over 10dB to less than 3dB [4].

For strongly nonlinear systems (e.g., forging press hydraulic control systems), a "complex function + A neural network compensation model is constructed. The Fourier transform module extracts stability-related frequency-domain features (e.g., 2Hz component amplitude during impact). A 3-hidden-layer backpropagation neural network—trained on 500+ sets of stable/unstable data—learns the mapping between complex function results and nonlinear errors. During analysis, the network dynamically corrects stability indicators (e.g., adjusting phase margin based on impact intensity). Simulation tests show this model reduces the average analysis error from over 30% to within 8% [4].

4.2. Building a theory-practice integration training system for engineering technicians

To bridge the theory-practice barrier (identified in 3.2.2), a multi-level training system focused on hands-on application is established.

At the basic level, scenario-based teaching materials replace abstract formulas with industrial cases. For each complex function method, materials define "application scenarios" (when to use), "simplified steps" (how to apply), and "result standards" (how to adjust parameters). For the residue theorem, steps are summarized as: "1. Collect system signals; 2. Establish transfer function via Laplace transform; 3. Calculate residues using a provided template; 4. Locate faults (residues 5x average indicate fault source)" [10]. This allows engineers to master operations in 2-3 sessions.

At the advanced level, a virtual simulation platform simulates typical systems (ADAS, power grid, UAV) and failure scenarios (sensor-induced pole deviation, load-induced oscillation). Engineers practice using complex functions (e.g., adjusting PID via Nyquist curves) and receive real-time feedback (e.g., correcting misinterpreted phase margin). Provided as a cloud service ($50/month per user) for SMEs, the platform increases the proportion of proficient SME engineers from 12% to over 40% [7].

4.3. Optimizing computational algorithms for multivariable control systems

To solve the computational complexity issue (identified in 3.2.3), a two-pronged optimization strategy is implemented.

DOI: 10.54254/2753-8818/2026.HZ29908

In terms of efficiency, a “PCA dimension reduction + GPU parallel computing” strategy is adopted. For high-dimensional matrices (e.g., 5×5 CNC matrix), PCA extracts stability-critical principal components (e.g., Z-axis feed rate-displacement) and eliminates low-correlation components (correlation <0.3), reducing matrix order by 40%-60%. GPU parallel computing accelerates pole solving and Nyquist curve plotting. For the 5-axis CNC system, this shortens verification time from 45 minutes to less than 6 minutes [5].

In terms of numerical stability, an ill-conditioned matrix preprocessing method is used. For matrices with condition numbers >10^5 (e.g., 10^6 clean room matrix), Tikhonov regularization adds a small term to diagonal elements, reducing the condition number to <10^3. The QR decomposition algorithm solves poles to avoid inversion errors. For the clean room system, this reduces pole position error from 15% to less than 2% [5]. A “result verification mechanism” is added: after complex function analysis, a time-domain step response test checks consistency (deviation >5% triggers recheck).

5. Conclusion

5.1. Key findings

This study yields three core findings. Regarding positive influences, complex functions enhance linear system stability judgment: the Laplace transform reduces conveyor belt verification time from 2.5 hours to 18 minutes (error <2%); the Nyquist criterion adjusts boiler water level phase margin to 20dB. They also strengthen fault prevention: Fourier transform predicts reactor runaway 2-3 hours in advance; the residue theorem shortens wind turbine repair time by 40%

Three critical problems are identified: poor nonlinear adaptability (robotic arm deviation >10dB, strong nonlinear error >30%); theory-practice barrier (35% global engineers proficient in Nyquist, 12% in SMEs); high multivariable complexity (CNC verification 45 minutes, clean room pole error 15%).

Targeted suggestions address these issues: hybrid frameworks reduce nonlinear errors to <8%; training systems increase proficient SME engineers to >40%; algorithm optimization shortens multivariable analysis time to <6 minutes (pole error <2%).

5.2. Research significance

Commercially, optimized methods shorten control system verification cycles by 30%-50% (e.g., ADAS from 2-3 hours to 15-20 minutes), reduce enterprise losses by over 40% (petrochemicals save $110,000/year), and cut SME commissioning costs by 50%.

Socially, the research ensures infrastructure safety: optimized Nyquist maintains grid frequency deviation <±0.2Hz for 99.5% of time; improved pole distribution reduces UAV attitude recovery time to 0.3 seconds. It also elevates the industrial control sector’s technical level, supporting the manufacturing/transportation intelligent transformation.

5.3. Limitations and future studies

This study has two limitations: it relies on secondary data (no field tests for the neural network model); it focuses on traditional industries (no exploration in quantum/biological control) .

Future research will: 1. Conduct 3-6 month field tests (e.g., applying the hybrid framework to forging press systems) to optimize parameters; 2. Expand to emerging fields (e.g., quantum bit

DOI: 10.54254/2753-8818/2026.HZ29908

stability via complex plane poles, cell culture signal decomposition via Fourier transform) and combine 5G/edge computing to improve distributed system real-time performance.
